Design and Analysis of Algorithms (VI)

Simplex Algorithm

Guoqiang Li

School of Software, Shanghai Jiao Tong University

Homework

• Assignment 2 is announced! (deadline Apr. 16)

LP

$$\max x_1 + 6x_2 + 13x_3$$

$$x_1 \le 200$$

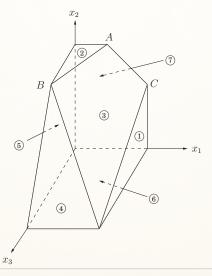

$$x_2 \le 300$$

$$x_1 + x_2 + x_3 \le 400$$

$$x_2 + 3x_3 \le 600$$

$$x_1, x_2, x_3 \ge 0$$

The Example

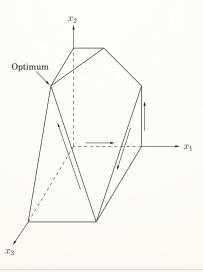

LP

- The point of final contact is the optimal vertex: (0, 300, 100), with total profit \$3100.
- Q: How would the simplex algorithm behave on this modified problem?
- A possible trajectory

$$\frac{(0,0,0)}{\$0} \to \frac{(200,0,0)}{\$200} \to \frac{(200,200,0)}{\$1400} \to \frac{(200,0,200)}{\$2800} \to \frac{(0,300,100)}{\$3100}$$

The Example

In the shortest path problem, we are given a weighted, directed graph G = (V, E), with weight function $w : E \to R$ mapping edges to real-valued weights, a source vertex s, and destination vertex t. We wish to compute the weight of a shortest path from s to t.

 $\max d_t$

$$d_{v} \leq d_{u} + w(u, v) \quad (u, v) \in E$$

$$d_{s} = 0$$

$$d_{i} \geq 0 \qquad i \in V$$

Let $S = \{S \subseteq V : s \in S, t \notin S\}$; that is, S is the set of all s-t cuts in the graph. Then we can model the shortest s-t path problem with the following integer program,

$$\min \sum_{e \in E} w_e x_e$$

$$\sum_{e \in \delta(S)} x_e \ge 1 \quad S \in \mathcal{S}$$

$$x_e \in \{0, 1\} \quad e \in E$$

where $\delta(S)$ is the set of all edges that have one endpoint in S and the other endpoint not in S.

- Can we relax the restriction $x_e \in \{0, 1\}$ to $0 \le x_e \le 1$?
- How about $x_e \ge 0$?

LP and Its Dual

Primal LP

$\max c^T \mathbf{x}$ $\mathbf{x} \geq 0$

Dual LP

$$\begin{array}{ll}
\max c^T \mathbf{x} & \min \mathbf{y}^T b \\
A\mathbf{x} \le b & \mathbf{y}^T A \ge c^T \\
\mathbf{x} \ge 0 & \mathbf{y} \ge 0
\end{array}$$

Primal LP:

$$\begin{aligned} & \max \ c_1x_1+\dots+c_nx_n\\ a_{i1}x_1+\dots+a_{in}x_n \leq b_i & \text{for } i \in I\\ a_{i1}x_1+\dots+a_{in}x_n = b_i & \text{for } i \in E\\ & x_j \geq 0 & \text{for } j \in N \end{aligned}$$

Dual LP:

$$\min b_1 y_1 + \dots + b_m y_m$$

$$a_{1j} y_1 + \dots + a_{mj} y_m \ge c_j \quad \text{for } j \in N$$

$$a_{1j} y_1 + \dots + a_{mj} y_m = c_j \quad \text{for } j \notin N$$

$$y_i \ge 0 \quad \text{for } i \in I$$

LP and Its Dual

$$\max x_1 + 6x_2 x_1 \le 200 x_2 \le 300 x_1 + x_2 \le 400 x_1, x_2 \ge 0$$

$$\min 200y_1 + 300y_2 + 400y_3$$

$$y_1 + y_3 \ge 1$$

$$y_2 + y_3 \ge 6$$

$$y_1, y_2, y_3 \ge 0$$

$$\min \sum_{e \in E} w_e x_e$$

$$\sum_{e \in \delta(S)} x_e \ge 1 \quad S \in \mathcal{S}$$
$$x_e \ge 0 \qquad e \in E$$

$$\max \sum_{S \in \mathcal{S}} y_S$$

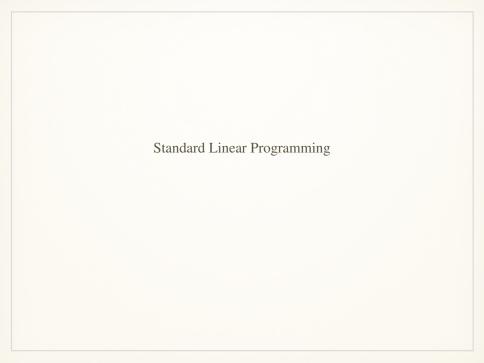

$$\sum_{S \in \mathcal{S}, e \in \delta(S)} y_S \le w_e \quad e \in E$$
$$y_S \ge 0 \qquad S \in \mathcal{S}$$

Complementary Slackness

Theorem

Assume LP problem (P) has a solution x^* and its dual problem (D) has a solution y^* .

- If $x_i^* > 0$, then the *j*-th constraint in (D) is binding.
- ② If the *j*-th constraint in (D) is not binding, then $x_i^* = 0$.
- 3 If $y_i^* > 0$, then the *i*-th constraint in (P) is binding.
- 4 If the *i*-th constraint in (P) is not binding, then $y_i^* = 0$.

A general linear program has many degrees of freedom:

- 1 It can be either a maximization or a minimization problem.
- 2 Its constraints can be equations and/or inequalities.
- **3** The variables are often restricted to be **nonnegative**, but they can also be unrestricted in sign.

We will now show that these various LP options can all be reduced to one another via simple transformations.

To turn a maximization problem into a minimization (or vice versa), multiply the coefficients of the objective function by -1.

To turn an inequality constraint like $\sum_{i=1}^{n} a_i x_i \leq b$ into an equation, introduce a new variable s and use

$$\sum_{i=1}^{n} a_i x_i + s = b$$

$$s > 0$$

This *s* is called the slack variable for the inequality.

To change an equality constraint into inequalities is easy: rewrite ax = b as the equivalent pair of constraints $ax \le b$ and $ax \ge b$.

Finally, to deal with a variable *x* that is unrestricted in sign, do the following:

- Introduce two nonnegative variables, $x^+, x^- \ge 0$.
- Replace x, wherever it occurs in the constraints or the objective function, by $x^+ x^-$.

Standard Form

We can reduce any LP into an LP of a much more constrained kind that we call the standard form:

- the variables are all nonnegative.
- the constraints are all equations.
- and the objective function is to be minimized.

$$\begin{array}{lll} \max x_1 + 6x_2 & \min -x_1 - 6x_2 \\ x_1 \leq 200 & x_1 + s_1 = 200 \\ x_2 \leq 300 & \Longrightarrow & x_2 + s_2 = 300 \\ x_1 + x_2 \leq 400 & x_1 + x_2 + s_3 = 400 \\ x_1, x_2 \geq 0 & x_1, x_2, s_1, s_2, s_3 \geq 0 \end{array}$$

General Description

Simplex

let v be any *vertex* of the feasible region, while there is a *neighbor* v' of v with better objective value: set v = v'

Vertices and Neighbors

Definition

Each vertex is the unique point at which some subset of hyperplanes meet.

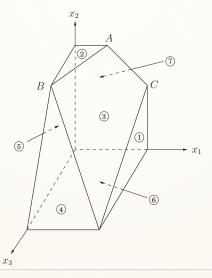

Pick a subset of the inequalities. If there is a unique point that satisfies them with equality, and this point happens to be feasible, then it is a vertex.

Each vertex is specified by a set of n inequalities (say there are n variables).

Definition

Two vertices are neighbors if they have n-1 defining inequalities in common.

The Example

The Algorithm

On each iteration, simplex has two tasks:

- **1** Check whether the current vertex is optimal (and if so, halt).
- 2 Determine where to move next.

Both tasks are easy if the vertex is at the origin. If the vertex is elsewhere, we transform the coordinate system to move it to the origin.

The Convenience for the Origin

Suppose we have some generic LP:

$$\max c^T \mathbf{x}$$
$$A\mathbf{x} \le b$$
$$\mathbf{x} \ge 0$$

where **x** is the vector of variables, $\mathbf{x} = (x_1, \dots, x_n)$.

Suppose the origin is feasible. Then it is certainly a vertex, since it is the unique point at which the n inequalities

$$\{x_1\geq 0,\ldots,x_n\geq 0\}$$

are tight.

Task 1 in the Origin

Lemma

The origin is optimal if and only if all $c_i \leq 0$.

Proof

If all $c_i \le 0$, then considering the constraints $x \ge 0$, we can't hope for a better objective value.

Conversely, if some $c_i > 0$, then the origin is not optimal, since we can increase the objective function by raising x_i .

Task 2 in the Origin

We can move by increasing some x_i for which $c_i > 0$.

Q: How much can we increase it?

A: Until we hit some other constraint.

We release the tight constraint $x_i \ge 0$ and increase x_i until some other inequality, previously loose, now becomes tight.

We have exactly n tight inequalities, so we are at a new vertex.

An Example

$$\max 2x_1 + 5x_2$$

$$2x_1 - x_2 \le 4$$

$$x_1 + 2x_2 \le 9$$

$$-x_1 + x_2 \le 3$$

$$x_1 \ge 0$$

$$x_2 \ge 0$$

Vertex Elsewhere

The trick is to transform u into the origin, by shifting the coordinate system from the usual (x_1, \ldots, x_n) to the "local view" from u.

These local coordinates consist of distances y_1, \ldots, y_n to the n hyperplanes (inequalities) that define and enclose u.

If one of these enclosing inequalities is $a_i \cdot x \le b_i$, then the distance from a point x to that particular "wall" is

$$y_i = b_i - a_i \cdot x$$

The *n* equations of this type, one per wall, define the y_i 's as linear functions of the x_i 's, and this relationship can be inverted to express the x_i 's as a linear function of the y_i 's.

An Example

$$\max 2x_{1} + 5x_{2}$$

$$2x_{1} - x_{2} \le 4$$

$$x_{1} + 2x_{2} \le 9$$

$$-x_{1} + x_{2} \le 3$$

$$x_{1} \ge 0$$

$$x_{2} \ge 0$$

$$\max 15 + 7y_1 - 5y_2$$

$$y_1 + y_2 \le 7$$

$$3y_1 - 2y_2 \le 3$$

$$y_2 \ge 0$$

$$y_1 \ge 0$$

$$-y_1 + y_2 \le 3$$

An Example

$$\max 15 + 7y_1 - 5y_2$$

$$y_1 + y_2 \le 7$$

$$3y_1 - 2y_2 \le 3$$

$$y_2 \ge 0$$

$$y_1 \ge 0$$

$$-y_1 + y_2 \le 3$$

$$\max 22 - 7/3z_1 - 1/3z_2$$

$$-1/3z_1 + 5/3z_2 \le 6$$

$$z_1 \ge 0$$

$$z_2 \ge 0$$

$$1/3z_1 - 2/3z_2 \le 1$$

$$1/3z_1 + 1/3z_2 \le 4$$

Rewriting the LP

We can rewrite the entire LP in terms of the y's.

This doesn't fundamentally change, but expresses it in a different coordinate frame.

The revised "local" LP has the following three properties:

- ① It includes the inequalities $y \ge 0$, which are simply the transformed versions of the inequalities defining u.
- $\mathbf{2}$ *u* itself is the origin in **y**-space.
- 3 The cost function becomes $\max c_u + \tilde{c}^T \mathbf{y}$, where c_u is the value of the objective function at u and \tilde{c} is a transformed cost vector.

The Starting Vertex

In a general LP, the origin might not be feasible and thus not a vertex.

It turns out that finding a starting vertex can be reduced to an LP and solved by simplex!

Start with any linear program in standard form:

$$\min c^T \mathbf{x}$$
 such that $\mathbb{A}\mathbf{x} = b$ and $x \ge 0$

We make sure that the right-hand sides of the equations are all nonnegative: if $b_i < 0$, multiply both sides of the *i*-th equation by -1.

The Starting Vertex

Then we create a new LP as follows:

- Create m new artificial variables $z_1, \ldots, z_m \ge 0$, where m is the number of equations.
- Add z_i to the left-hand side of the *i*-th equation.
- Let the objective, to be minimized, be $z_1 + z_2 + \ldots + z_m$.

An Example

$$\min -x_1 - 6x_2$$

$$x_1 + s_1 = 200$$

$$x_2 + s_2 = 300$$

$$x_1 + x_2 + x_3 = 400$$

$$x_1, x_2, x_3 \ge 0$$

$$\min z_1 + z_2 + z_3$$

$$x_1 + s_1 + z_1 = 200$$

$$x_2 + s_2 + z_2 = 300$$

$$x_1 + x_2 + x_3 + z_3 = 400$$

$$x_1, x_2, x_3 \ge 0$$

$$z_1, z_2, z_3 \ge 0$$

The Starting Vertex

For this new LP, it's easy to come up with a starting vertex, namely, the one with $z_i = b_i$ for all i and all other variables zero.

Therefore we can solve it by simplex, to obtain the optimum solution.

There are two cases:

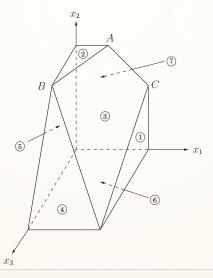

- If the optimum value of $z_1 + \ldots + z_m$ is zero, then all z_i 's obtained by simplex are zero, and hence from the optimum vertex of the new LP we get a starting feasible vertex of the original LP.
- ② If the optimum objective turns out to be positive: We tried to minimize the sum of the z_i 's, but it cannot be zero. This means that the original linear program is infeasible.

Degeneracy

A vertex is degenerate if it is the intersection of more than n faces of the polyhedron, say n + 1.

It means that if we choose any one of n sets of n+1 inequalities and solve the corresponding system of these linear equations in n unknowns, we'll get the same solution in all n+1 cases.

An Example

Degeneracy

This is a serious problem: simplex may return a suboptimal degenerate vertex simply because all its neighbors are identical to it and thus have no better objective.

If we modify simplex so that it detects degeneracy and continues to hop from vertex to vertex despite lack of any improvement in the cost, it may end up looping forever.

Degeneracy

One way to fix this is by a perturbation: change each b_i by a tiny random amount to $b_i \pm \varepsilon_i$

This doesn't change the essence of the LP, but it has the effect of differentiating between the solutions of the linear systems.

Unboundedness

In some cases an LP is unbounded, in that its objective function can be made arbitrarily large (or small, if it's a minimization problem).

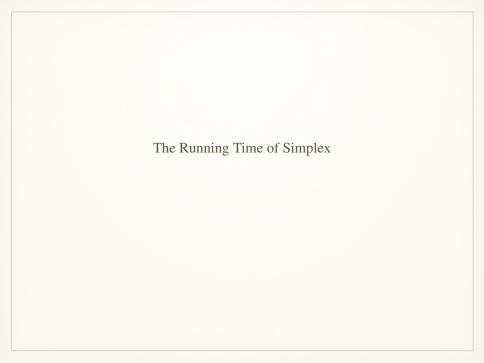

If this is the case, simplex will discover it:

- In exploring the neighborhood, it will notice that taking out an inequality and adding another leads to an underdetermined system of equations.
- The space of solutions contains a whole line across which the objective can become larger and larger, all the way to ∞.

In this case simplex halts and complains.

An Example

 $\max x_1 + x_2$ $x_1 - x_2 \ge 0$ $x_1, x_2 \ge 0$

Q: What is the running time of simplex, for a generic linear program:

$$\max c^T \mathbf{x}$$
 such that $\mathbb{A}\mathbf{x} \leq 0$ and $\mathbf{x} \geq 0$

where there are n variables and \mathbb{A} contains m inequality constraints?

It is an iterative algorithm that proceeds from vertex to vertex. Let u be the current vertex.

Each of its neighbors shares n-1 of these inequalities, so u can have at most $n \cdot m$ neighbors.

A naive way for an iteration:

- check each potential neighbor to see whether it really is a vertex of the polyhedron,
- 2 determine its cost.

Finding the cost is quick, just a dot product.

Checking whether it is a true vertex involves: solve a system of n equations and check whether the result is feasible.

By Gaussian elimination this takes $O(n^3)$ time, giving total $O(mn^4)$ per iteration.

A much better way: the mn^4 can be improved to mn.

Recall the local view from vertex u. The per-iteration overhead of rewriting the LP in terms of the current local coordinates is just O((m+n)n).

The local view changes only slightly between iterations, in just one of its defining inequalities.

To select the **best** neighbor, we recall that the objective function is of the form

$$\max c_u + \tilde{c} \cdot \mathbf{y}$$

where c_u is the value of the objective function at u.

This immediately identifies a promising direction to move: we pick any $\tilde{c}_i > 0$.

Since the rest of the LP has now been rewritten in terms of the \mathbf{y} -coordinates, it is easy to determine how much y_i can be increased before some other inequality is violated.

Q: How many iterations could there be?

A: At most $\binom{m+n}{n}$, i.e., the number of vertices.

It is exponential in n.

And in fact, there are examples of LPs for which simplex does indeed take an exponential number of iterations.

Simplex is an exponential-time algorithm.

However, such exponential examples do not occur in practice, and it is this fact that makes simplex so valuable and so widely used.

A Notable Result

Smoothed analysis proposed by Daniel Spielman and Shanghua Teng is a way of measuring the complexity of an algorithm. It gives a more realistic analysis of the practical performance of the algorithm. It was used to explain that the simplex algorithm runs in exponential-time in the worst-case and yet in practice it is a very efficient algorithm, which was one of the main motivations for developing smoothed analysis. The authors received the 2008 Gödel Prize and the 2009 Fulkerson Prize.
